Spontaneous spinal cerebrospinal fluid leaks and minor skeletal features of Marfan syndrome: a microfibrilopathy

IRIS SCHRIVER, M.D., WOUTER I. SCHIEVINK, M.D., MAURICE GODFREY, PH.D., FREDRIC B. MEYER, M.D., AND UTA FRANCKE, M.D.

Howard Hughes Medical Institute and the Departments of Genetics and Pediatrics, Stanford University School of Medicine, Stanford, California; Cedars-Sinai Neurosurgical Institute, Los Angeles, California; Department of Pediatrics and Center for Human Molecular Genetics, University of Nebraska Medical Center, Omaha, Nebraska; and Department of Neurologic Surgery, Mayo Clinic, Rochester, Minnesota

Objective. Spontaneous spinal cerebrospinal fluid (CSF) leaks are increasingly recognized as a cause of postural headaches. The authors examined a group of patients suffering from spontaneous spinal CSF leaks who also had minor skeletal features of Marfan syndrome for abnormalities of fibrillin-containing microfibrils.

Methods. Patients with spontaneous CSF leaks were evaluated for the clinical characteristics of connective tissue disorders. Skin biopsies were obtained in three patients with skeletal manifestations that constitute part of the Marfan syndrome phenotype. Cultured fibroblasts were studied for fibrillin-1 synthesis and incorporation into the extracellular matrix (ECM) by performing quantitative metabolic labeling and immunohistochemical analysis. Among 20 consecutive patients found to have spinal CSF leaks, four (20%) exhibited minor skeletal features of Marfan syndrome, but lacked any ocular or cardiovascular abnormalities. The mean age of these patients (30 years) was lower than that of the 16 patients without skeletal abnormalities (44 years; p = 0.01). Abnormalities in fibrillin-1 metabolism and immunostaining were detected in all three patients with the skeletal abnormalities who underwent examination, but not in a control patient without these skeletal manifestations.

Conclusions. Twenty percent of patients who experience spontaneous spinal CSF leaks have minor skeletal features of Marfan syndrome. The authors demonstrated abnormalities in fibrillin-1 protein deposition in all patients examined, but only one person was found to have a fibrillin-1 abnormality typically found in classic Marfan syndrome. The results indicate that there is a heterogeneous involvement of other components of ECM microfibrils at the basis of this cerebrospinal manifestation. In addition, the authors identified a connective-tissue etiological factor in a group of disorders not previously classified as such.

Key Words • fibrillin • headache • intracranial hypotension • cerebrospinal fluid leak • Marfan syndrome • microfibrilopathy • pulse-chase analysis • fibrillin immunofluorescence

Connective tissue spectrum abnormalities associated with spontaneous cerebrospinal fluid leaks: a prospective study

Eyal Reinstein*,1, Mitchel Pariani1, Serguei Bannykh2, David L Rimoin*,1 and Wouter I Schievink3

We aimed to assess the frequency of connective tissue abnormalities among patients with cerebrospinal fluid (CSF) leaks in a prospective study using a large cohort of patients. We enrolled a consecutive group of 50 patients, referred for consultation because of CSF leak. All patients have been carefully examined for the presence of connective tissue abnormalities, and based on findings, patients underwent genetic testing. Ancillary diagnostic studies included echocardiography, eye exam, and histopathological examinations of skin and dura biopsies in selected patients. We identified nine patients with heritable connective tissue disorders, including Marfan syndrome, Ehlers–Danlos syndrome and other unclassified forms. In seven patients, spontaneous CSF leak was the first noted manifestation of the genetic disorder. We conclude that spontaneous CSF leaks are associated with a spectrum of connective tissue abnormalities and may be the first noted clinical presentation of the genetic disorder. We propose that there is a clinical basis for considering spontaneous CSF leak as a clinical manifestation of heritable connective tissue disorders, and we suggest that patients with CSF leaks should be screened for connective tissue and vascular abnormalities.

Keywords: hereditary disorders of connective tissue; spontaneous cerebrospinal fluid leak; positional headache screening

17/50 = 34%
Connective tissue disorders in spontaneous intracranial hypotension

- Abnormalities on EM in about 20% of patients
- Aortic dilatation in about 20% of patients
- Intracranial aneurysms in about 10% of patients
- Family history rare (<.5%)
Environmental factors

- More or less trivial trauma (30 - 50%)
- Seasonal variation (peak in spring)
- Bariatric surgery
- Spider bite
Clinical Manifestations

• Non-positional headache  
• Reverse orthostatic headache  
• Exertional headache  
• Valsalva-induced headache  
• Head-shaking headache  
• Latter half of the day headache  
• Trigeminal neuralgia
Burden of headache

Epidemiology and comorbidity of headache

Rigmor Jensen, Lars J Stovner

The burden associated with headache is a major public health problem, the true magnitude of which has not been fully acknowledged until now. Globally, the percentage of the adult population with an active headache disorder is 47% for headache in general, 10% for migraine, 38% for tension-type headache, and 3% for chronic headache that lasts for more than 15 days per month. The large costs of headache to society, which are mostly indirect through loss of work time, have been reported. On the individual level, headaches cause disability, suffering, and loss of quality of life that is on a par with other chronic disorders. Most of the burden of headache is carried by a minority who have substantial and complicating comorbidities. Renewed recognition of the burden of headache and increased scientific interest have led to a better understanding of the risk factors and greater insight into the pathogenic mechanisms, which might lead to improved prevention strategies and the early identification of patients who are at risk.

Spontaneous Spinal Cerebrospinal Fluid Leaks and Intracranial Hypotension

Wesley L. Shovlin, MD

**A** patient presents with a new headache that occurs shortly after assuming an upright position and is relieved by lying down. Although subclassified headaches pattern is well known, following a diagnostic lumbar puncture, the symptoms of intracranial hypotension is not well recognized and the patient may be diagnosed with migraines, tension headaches, or vertigo. This has been a typical scenario for many patients experiencing spontaneous intracranial hypotension. The spontaneous form of intracranial hypotension was first described in 1938 and much has been learned about this syndrome, particularly since the early 1990s. However, initial diagnostic approaches have not maintained the norm. Unfamiliarity with spontaneous intracranial hypotension among physicians in general and the internist-trained spectrum of clinical and radiologic manifestations may contribute to a delay in diagnosis that often is measured in months or even years and decades.

**EVIDENCE ACQUISITION**

In the systematic review of animal studies in MEDLINE (1950-2005) and EMBASE (1980-2005) using the terms intracranial hypotension, CSF leak, low-pressure headache, and CSF hypotension, reference lists of these articles and ongoing investigations in this area were also used. Clinical trials were not available, and prospective studies were selected over retrospective studies. Selected articles were largely those published within the past 10 years and having adequate documentation and adequate clinical information. Also, other articles were also included if they were commonly referenced and highly regarded.

**EVIDENCE SYNTHESIS**

**Epidemiology**

Cases considered an exceedingly rare disorder, recent evidence suggests that spontaneous intracranial hypotension is not that rare and has to be considered an important cause of new daily persistent headaches, particularly among young and middle-aged individuals. In the past, our knowledge re...
MRI Findings - Caveats

- Normal MRI in approximately 20% of patients
- MRI often normalizes in spite of persistent CSF leak
- MRI may become abnormal during course of disease
Diagnostic evaluation of SIH — A practical approach

Towards a non-invasive diagnostic work up, i.e., no lumbar puncture and minimizing ionizing radiation

MRI brain
MRI spine/MRMyelography

Epidural blood patching
Percutaneous fibrin glue glue placement
Surgery (+for PDPH)
Detection of spinal CSF Leak – is it necessary?

- MRI/MR-myelography
- Radionuclide Cisternography
- CT-Myelography/Digital Subtraction Myelography (DSM)
- Dynamic CT-myelography
- Intrathecal gado-enhanced MRI
When urgent treatment is required such as with coma

Knowledge of exact site of CSF leak required

Intrathecal infusion of saline or artificial CSF*

Bedrest
Oral hydration
Oral caffeine
Abdominal binder

Epidural blood patch (repeat if necessary)

Percutaneous placement of fibrin sealant†

Surgical CSF leak repair†

* When urgent treatment is required such as with coma†

Knowledge of exact site of CSF leak required
Advances in treatment for SIH

• Understanding the anatomy of CSF leaks

  Through – advances in imaging
  intraoperative observations
Are advances in care available to patients with spontaneous intracranial hypotension?

- Diagnostic delay
- Access to medical care
  - Insurance
  - Across state lines
  - Across national borders
- Appropriate systemic organization
- Appropriate reimbursement (e.g., DSM)
Cause of intracranial hypotension is

• Spinal CSF leak

• Pooling of CSF

• Inadequate CSF production?
• Rapid CSF absorption?

• ? CSF rhinorrhea–otorrhoea ? NEVER!

Lack of causal association between spontaneous intracranial hypotension and cranial cerebrospinal fluid leaks

Classification of Spontaneous Spinal CSF Leaks

• Type 1: Dural tear
• Type 2: Arachnoid cyst
• Type 3: CSF-venous fistula
• Type 4: Indeterminate

ABSTRACT
Objective. Spontaneous spinal CSF leaks cause spontaneous intracranial hypotension but no systematic study of the different types of these CSF leaks has been reported. Based on our experience with spontaneous intracranial hypotension, we propose a classification system of spontaneous spinal CSF leaks.

Methods. We reviewed the medical records, radiographic studies, operative notes, and any intraoperative photographs of a group of consecutive patients with spontaneous intracranial hypotension.

Results. The mean age of the 569 patients (373 [65.7%] women) was 65.7 years. Three types of CSF leaks could be identified. Type 1 CSF leaks consisted of a dural tear (331 patients [26.6%]) and these were almost exclusively associated with an extradural CSF collection. Type 1a represented sphenoid CSF leaks (162 patients [14.6%]) and type 1b represented transdural CSF leaks (119 patients [10.8%]). Type 2 CSF leaks consisted of meningeal diverticula (240 patients [20.3%]) and were the source of an extradural CSF collection in 53 of these patients (22.1%). Type 2a represented simple diverticula (96.8%) and type 2b represented complex meningeal diverticula (3.2%). Type 3 CSF leaks consisted of direct CSF-venous fistulas (14 patients [0.5%]) and these were not associated with extradural CSF collections. A total of 103 patients (24.7%) had an indeterminate type and extradural CSF collections were noted in 4.5 (5.5%) of these patients.

Conclusions. We identified 3 types of spontaneous spinal CSF leaks in this observational study: the dural tear, the meningeal diverticulum, and the CSF-venous fistula. These 3 types and the presence or absence of extradural CSF form the basis of a comprehensive classification system.

GLOSSARY
CSF – cerebrospinal fluid
DHI – digital subtraction angiography

Spontaneous intracranial hypotension is an enigmatic disorder that has a variable complex of symptoms but an orthostatic headache is by far the most common presenting symptom. Spontaneous intracranial hypotension may be caused by a spontaneous spinal CSF leak or possibly by pooling of CSF in the spine. Spontaneous CSF leaks at the level of the skull base, e.g., CSF rhinorrhea, do not cause spontaneous intracranial hypotension.

Spontaneous spinal CSF leaks have been visualized with a variety of imaging techniques over the years and several surgical series have been reported describing various intraoperative findings. However, no systematic study of the different types of spontaneous spinal CSF leaks has been reported and a classification system of these spinal CSF leaks is not available. We now report a study of a large number of patients with spontaneous intracranial hypotension, the great majority of whom underwent detailed spinal imaging and half of whom underwent surgical repair of the underlying spinal pathology. Based on the results of this study, we propose a comprehensive but simple classification system of spontaneous spinal CSF leaks.

METHODS: We reviewed the medical records, radiographic studies, operative notes, and any intraoperative photographs of a group of consecutive patients with spontaneous intracranial hypotension evaluated between March 1, 2009, and August 31, 2015. Since January 1, 2001, all patients with spontaneous intracranial hypotension evaluated by us at Coto de Caza Medical Center have been

### Abstract

Spontaneous spinal CSF leaks cause spontaneous intracranial hypotension but to systematically study the different types of these CSF leaks has not been reported. In this paper, we present a classification system of spontaneous spinal CSF leaks.

**Methods:** We reviewed the medical records of 568 patients (Mar 1, 2009-Aug 31, 2015) and 70 patients (Apr 4, 2018-Sept 17, 2018). The classification system was developed based on clinical presentation and imaging findings.

**Results:** Of the 568 patients, 156 (27%) had type 1 CSF leaks, 240 (42%) had type 2 CSF leaks, 14 (2.5%) had type 3 CSF leaks, and 8 (1.5%) had type 4 CSF leaks. In the follow-up period, 145 patients (26%) had type 1 CSF leaks, 109 patients (19%) had type 2 CSF leaks, 30 patients (5.3%) had type 3 CSF leaks, and 11 patients (2%) had type 4 CSF leaks.

**Conclusion:** This classification system of spontaneous spinal CSF leaks is a simple and comprehensive system for the diagnosis and management of these leaks.

False localizing sign of C1–2 cerebrospinal fluid leak in spontaneous intracranial hypotension

WOUTER I. SCHIEVINK, M.D., M. MARCEL MAYA, M.D., AND JAMES TOURJE, M.D.

Maxine Dunitz Neurosurgical Institute and Imaging Medical Group, Cedars-Sinai Medical Center, Los Angeles, California

Object. Spontaneous intracranial hypotension due to a spinal cerebrospinal fluid (CSF) leak is an important cause of new daily persistent headaches. Spinal neuroimaging is important in the treatment of these patients, particularly when direct repair of the CSF leak is contemplated. Retrospinal C1–2 fluid collections may be noted on spinal imaging and these are generally believed to correspond to the site of the CSF leak. The authors undertook a study to determine the significance of these C1–2 fluid collections.

Methods. The patient population consisted of a consecutive group of 25 patients (18 female and seven male) who were evaluated for surgical repair of a spontaneous spinal CSF leak. The mean age of the 18 patients was 38 years (range 13–72 years). All patients underwent computerized tomography myelography. Three patients (12%) had extensive retrospinal C1–2 fluid collections; the mean age of this woman and these two men was 41 years (range 39–43 years). The actual site of the CSF leak was located at the lower cervical spine in these patients and did not correspond to the site of the retrospinal C1–2 fluid collection.

Conclusions. A retrospinal fluid collection at the C1–2 level does not necessarily indicate the site of the CSF leak in patients with spontaneous intracranial hypotension. This is an important consideration in the treatment of these patients because therapy may be inadvertently directed at this site.

ABSTRACT

Objective: Spontaneous spinal CSF leaks are an important cause of new-onset headaches. Such leaks are reported to be particularly common at the cervico-thoracic junction. The authors undertook a study to determine the significance of these cervico-thoracic CSF leaks.

Methods: The patient population consisted of a consecutive group of 13 patients who underwent surgery for CSF leak repair based on CT myelography showing CSF extravasation at the cervico-thoracic junction but without any evidence of an underlying structural lesion.

Results: The mean age of the 9 women and 4 men was 41.2 years. Extensive extrathecal longitudinal CSF collections were demonstrated in 11 patients. At surgery, small leaking arachnoid cysts were found in 2 patients. In the remaining 11 patients, no clear source of CSF leakage could be identified at surgery. Resolution of symptoms was achieved in both patients with leaking arachnoid cysts, but in only 3 of the 11 patients with negative intraoperative findings. Postoperative spinal imaging was performed in 9 of the 11 patients with negative intraoperative findings and showed persistence of the longitudinal intraspinal extradural CSF. Further imaging revealed the site of the CSF leak to be ventral to the thoracic spinal cord. Five of these patients underwent microsurgical repair of the ventral CSF leak with resolution of symptoms in all 5 patients.

Conclusions: Cervico-thoracic extravasation of dye on myelography does not necessarily indicate the site of the CSF leak. Treatment directed at this site should not be expected to have a high probability of sustained improvement of symptoms. Neurology® 2015;84:2445-2448

False localizing sign of C1–2 cerebrospinal fluid leak in spontaneous intracranial hypotension

Wouter J. Scheinin, M.D., M. Marcel Mayo, M.D., and James Tourje, M.D.

Maxine Dunitz Neurosurgical Institute and Imaging Medical Group, Cedars-Sinai Medical Center, Los Angeles, California

Objective. Spontaneous intracranial hypotension due to a spinal cerebrospinal fluid (CSF) leak is an important cause of new or daily persistent headaches. Spinal neuroimaging is important in the treatment of these patients, particularly when direct repair of the CSF leak is contemplated. Retrospective C1–2 fluid collections may be noted on spinal imaging and are generally believed to correspond to the site of the CSF leak. The authors undertook a study to determine the significance of these C1–2 fluid collections.

Methods. The patient population consisted of a consecutive group of 16 patients (10 female and six male) who were evaluated for surgical repair of a spontaneous spinal CSF leak. The mean age of the 16 patients was 55 years (range 35–87 years). All patients underwent computed tomography myelography. Three patients (19%) had extensive retrospinal C1–2 fluid collections; the mean age of this woman and those two men was 52 years (range 49–63 years). The actual site of the CSF leak was located at the lower cervical spine in these patients and did not correspond to the site of the retrospinal C1–2 fluid collection.

Conclusions. A retrospinal fluid collection at the C1–2 level does not necessarily indicate the site of the CSF leak in patients with spontaneous intracranial hypotension. This is an important consideration in the treatment of these patients because surgery may be inadvertently directed at this site.

False localizing sign of cervico-thoracic CSF leak in spontaneous intracranial hypotension

ABSTRACT

Objectives. Spontaneous spinal CSF leaks are an important cause of new or daily headaches. Such leaks are reported to be particularly common at the cervico-thoracic junction. The authors undertook a study to determine the significance of these cervico-thoracic CSF leaks.

Methods. The patient population consisted of a consecutive group of 13 patients who underwent surgical repair for CSF leaks based on CT myelography showing CSF extravasation at the cervico-thoracic junction but without any evidence of an underlying structural lesion.

Results. The mean age of the 13 women and four men was 41.2 years. Extension of the retrospinal longitudinal CSF collections was demonstrated in 11 patients. At surgery, small leaking arteriovenous shunts were found in 10 patients. In the remaining 11 patients, no clear source of CSF leakage could be identified at surgery. Resolution of symptoms was achieved in both patients with leaking arteriovenous shunts, but in only 6 of the 12 patients with negative intraoperative findings. Postoperative spinal imaging was performed in 9 of the 11 patients with negative intraoperative findings and showed persistence of the longitudinal intrathecal extruded CSF. Further imaging revealed the site of the CSF leak to be extra-dural in the thoracic spinal cord. Five of these patients underwent diagnostic repair of the ventral CSF leak with resolution of symptoms in all 5 patients.

Conclusions. Cervico-thoracic extravasation of dye on myelography does not necessarily indicate the site of the CSF leak. Treatment directed at this site should not be expected to have a high probability of sustained improvement of symptoms.

Spontaneous intracranial hypotension due to a spinal cerebrospinal fluid (CSF) leak is a rare but increasingly recognized cause of postural headaches. The exact cause of these CSF leaks often remains unknown. The authors treated a 32-year-old man with a unique cause of spontaneous intracranial hypotension. He suffered an excruciating headache that was exacerbated by his being in an upright position. The results of four-vessel cerebral angiography were negative; however, magnetic resonance (MR) imaging of the brain revealed pachymeningeal enhancement and hindbrain herniation. A presumptive diagnosis of spontaneous intracranial hypotension was made. Myelography revealed extrathecal contrast material ventral to the cervical spinal cord as well as an unusual midline bone spur at C5–6. The patient’s symptoms did not resolve with the application of epidural blood patches, and he subsequently underwent an anterior approach to the C5–6 spur. After discectomy, a slender bone spur that had pierced the thecal sac was found. After its removal, the durar rent was closed using two interrupted prolene sutures. The patient was discharged home 2 days later. On follow up his symptoms had resolved, and on MR imaging the pachymeningeal enhancement had resolved and the cerebellar herniation had improved slightly.

Fig. 1. Postmyelography axial CT obtained at the C5–6 level, showing the bone spur protruding into the thecal sac and associated extrathecal contrast.

Brief Communication

A Novel Technique for Treatment of Intractable Spontaneous Intracranial Hypotension: Lumbar Dural Reduction Surgery

Wouter I. Schievink, MD

Background and Objective.—Spontaneous intracranial hypotension has become a well-described cause of headache particularly among young and middle-aged individuals. Treatment of the underlying spinal cerebrospinal fluid (CSF) leak is effective in relieving symptoms in the vast majority of patients but symptoms may become refractory. The author describes a novel surgical technique to treat intractable spontaneous intracranial hypotension.

Methods.—A lumbar laminectomy is performed, a strip of dura is resected, and the dural defect is closed. The resulting decrease in lumbar CSF volume is believed to increase intracranial CSF volume and pressure.

Results.—The technique was utilized in a patient who suffered with intractable positional headaches because of a spinal CSF leak for 6 years in spite of numerous surgical and nonsurgical therapies. Significant improvement of symptoms was sustained during a 1-year period of follow-up.

Conclusion.—Dural reduction surgery may be considered in carefully selected patients with intracranial hypotension.

A Wearable Epidural Catheter Infusion System for Patients With Intractable Spontaneous Intracranial Hypotension

Wouter I. Schievink, MD,* Howard L. Rosner, MD,† and Charles Louy, MD, PhD†

Background and Objectives: Spontaneous intracranial hypotension is an important cause of secondary headaches, and most patients respond well to epidural blood patching or direct repair of the underlying spinal cerebrospinal fluid leak. However, options are limited for those patients who have exhausted these traditional treatments, especially when spinal imaging is normal. We describe a wearable epidural catheter infusion system for patients with intractable spontaneous intracranial hypotension.

Methods: Six patients with intractable spontaneous intracranial hypotension (4 women and 2 men; mean age, 53 years; mean duration of symptoms, 50 months) underwent placement of a permanent indwelling spinal epidural catheter attached to an external infusion pump. The Migraine Disability Assessment questionnaire was used to assess the severity of the symptoms, before and during treatment.

Results: The infusion resulted in complete or near-complete symptom relief in 5 of 6 patients (Migraine Disability Assessment score decreased from grade IV to grade I or II). However, the epidural catheter infusion system was removed in 2 patients because of infection, in 1 patient because of delayed failure to provide adequate symptom control, and in 1 patient because of minimal symptom relief. Two patients reported excellent and sustained symptom relief over 27 and 36 months of follow-up.

Conclusions: This wearable epidural catheter infusion system showed promising efficacy results but the high rate of complications limits its use to a very select group of patients.

(Reg Anesth Pain Med 2015;40: 49–51)

METHODS

Patients

Six patients with spontaneous intracranial hypotension were recruited for this trial (Table 1). The insertions of the spinal epidural catheters were performed between June 2009 and January 2010. Four of the patients were women and the mean age of the group was 53 years (range, 40–79 years). Duration of symptoms varied from 24 to 105 months (mean, 50 months). Orthostatic headache was the most prominent complaint in all patients. Neurologic examination and brain magnetic resonance imaging (MRI) findings were normal in all patients. Initial opening pressure at time of lumbar puncture was below normal in all patients (range, negative to 5 cm H₂O). Spinal MRI and computed tomography-myelography was performed in all patients and showed an extensive CSF leak in 1 patient and multiple spinal meningeal diverticula in 2 patients. Spinal imaging was entirely normal in the remaining 3 patients. Thus, the presence of a spinal CSF leak could not be established in 5 of the 6 patients. All patients had undergone 2 or more surgical treatments directed at the CSF leak or largest spinal meningeal diverticulum without relief of symptoms.
